Impossible Differential Cryptanalysis of 3D Block Cipher

Mohsen Shakiba, Mohammad Dakhilalian, and Hamid Mala

Abstract—3D is a secret-key block cipher, designed to secure and fast encryption of large amounts of data. This block cipher uses multi-dimensional states to generalize the design of Rijndael. Thus, while maintaining the benefits of the AES design, 3D operates on 512-bit blocks of data and can also be used as a cryptographic primitive in the cryptographic systems with the large internal states. Since its proposal in 2008, the cryptanalysis of 3D has been considered in several papers. While the previous impossible differential attacks on 3D cipher can analyze up to 10 rounds of the cipher, this paper, using a new 6-round impossible differential, presents an impossible differential attack on 11 rounds of 3D. The proposed distinguisher begins in the input of AddRoundKey operation of round 3, and ends in the output of ShiftRows of round 8. Results show that the proposed attack on 11-round of 3D cipher requires about $2^{501}$ chosen plaintexts and a time complexity of about $2^{955}$ 11-round encryptions.

Index Terms—Block ciphers, Cryptanalysis, Impossible Differential, Symmetric cryptography

I. INTRODUCTION

The block cipher 3D is an AES-based block cipher proposed by Nakahara at CANS 2008 [1]. This block cipher operates on 512-bit blocks and supports a 512-bit secret-key. Inspired from the design of AES [2], the main round transformations of 3D are basically the same as those of AES, while it operates on larger blocks of data and a larger key size. In fact, 3D cipher puts four AES states in parallel and applies the diffusion of AES in two different directions in every two rounds in turn. Security of 3D block cipher has been considered through several cryptanalysis methods including multiset [1], [3], impossible differential [1], [3]-[4], truncated differential [5] and square attack [6]. Results of key recovery attacks on 3D block cipher are summarized in Table I. According to this table, the best known attack on 3D is a truncated differential attack which can be mounted on 13 rounds of it [5]. Two known-key distinguishers on 9.75-round and 15-round 3D have been also proposed in [3] and [7], respectively.

In this paper we focus on impossible differential cryptanalysis of 3D. Impossible differential cryptanalysis, an extension of the differential attack [8], was first introduced by Knudsen [9] and Biham [10] to analyze DEAL and Skipjack, respectively. This kind of attack uses differentials that hold with probability zero to derive the right key by discarding the wrong keys which lead to the impossible differential. This cryptanalysis technique has achieved considerable results on AES [11]-[14]. Also, for block cipher Camellia [15], which has been approved by NESSIE and the Japanese CRYPTREC projects, the best cryptanalytic results are obtained by the impossible differential attacks [16]-[18].

As it is seen in Table I, previous impossible differential analyses of 3D cipher are applicable up to 10 rounds [1], [3]-[4]. In this paper, using a new 6-round impossible differential (ID), we propose an impossible differential cryptanalysis of 11 rounds of 3D cipher. This attack requires about $2^{500.5}$ chosen plaintexts and $2^{955}$ memory accesses which is equivalent to about $2^{955}$ 11-round encryptions. Also, the attack needs about $2^{381}$ bytes of memory to store the intermediate values and the precomputations.

The rest of this paper is organized as follow. Section II provides a brief description of the 3D cipher. Section III introduces a new 6-round ID distinguisher of 3D. A new key recovery attack on 11 rounds of 3D is described in Section IV. Finally, the paper is concluded in Section V.

II. PRELIMINARIES AND A BRIEF DESCRIPTION OF 3D

The block cipher 3D is a 22-round SPN block cipher with 512-bit block length and 512-bit key. Each state in the cipher is composed of 64 bytes ($a_s, a_{s+1}, ..., a_{s+63}$) which are ordered column-wise as follows:

Moreover, a key scheduling algorithm generates 22 rounds of 512-bit subkeys, each with the same order and structure as the state. Like AES, each round of 3D consists of four transformations, each one is considered as a fraction of 0.25 of one round. Using the terminology of [1], these transformations are as follow:

- $\kappa$: bit-wise XOR with the 512-bit subkey of i-th round ($k_i$), equivalent to the AddRoundKey operation in the AES.
- $\gamma$: a byte-wise S-box layer with the 8-bit S-box of AES, equivalent to the SubBytes operation in the AES.
- $\theta_1, \theta_2$: two different byte transpositions equivalent to the ShiftRows operation of AES, applied in two different directions, respectively. $\theta_1$ and $\theta_2$ are applied in odd-numbered rounds and even-numbered rounds according to the following permutations, respectively:

$$
\begin{align*}
\theta_1 &= \begin{pmatrix}
 a_0 & a_1 & a_2 & a_3 & a_4 & a_5 & a_6 & a_7 \\
 a_8 & a_9 & a_{10} & a_{11} & a_{12} & a_{13} & a_{14} & a_{15} \\
 a_{16} & a_{17} & a_{18} & a_{19} & a_{20} & a_{21} & a_{22} & a_{23} \\
 a_{24} & a_{25} & a_{26} & a_{27} & a_{28} & a_{29} & a_{30} & a_{31} \\
 a_{32} & a_{33} & a_{34} & a_{35} & a_{36} & a_{37} & a_{38} & a_{39} \\
 a_{40} & a_{41} & a_{42} & a_{43} & a_{44} & a_{45} & a_{46} & a_{47} \\
 a_{48} & a_{49} & a_{50} & a_{51} & a_{52} & a_{53} & a_{54} & a_{55} \\
 a_{56} & a_{57} & a_{58} & a_{59} & a_{60} & a_{61} & a_{62} & a_{63}
\end{pmatrix}, \\
\theta_2 &= \begin{pmatrix}
 a_0 & a_1 & a_2 & a_3 & a_4 & a_5 & a_6 & a_7 \\
 a_8 & a_9 & a_{10} & a_{11} & a_{12} & a_{13} & a_{14} & a_{15} \\
 a_{16} & a_{17} & a_{18} & a_{19} & a_{20} & a_{21} & a_{22} & a_{23} \\
 a_{24} & a_{25} & a_{26} & a_{27} & a_{28} & a_{29} & a_{30} & a_{31} \\
 a_{32} & a_{33} & a_{34} & a_{35} & a_{36} & a_{37} & a_{38} & a_{39} \\
 a_{40} & a_{41} & a_{42} & a_{43} & a_{44} & a_{45} & a_{46} & a_{47} \\
 a_{48} & a_{49} & a_{50} & a_{51} & a_{52} & a_{53} & a_{54} & a_{55} \\
 a_{56} & a_{57} & a_{58} & a_{59} & a_{60} & a_{61} & a_{62} & a_{63}
\end{pmatrix}.
\end{align*}
$$

As it is discussed in [19], these two permutations could be unified in a single byte permutation with the same diffusion property.

- $\pi$: A 4x4 matrix multiplication is applied to columns of the state, equivalent to the MixColumns operation of AES.

The i-th round of an r-round 3D cipher $(0 \leq i \leq r-1)$ is denoted by $\pi \circ \theta_1 \circ \text{AddRoundKey} \circ \text{ShiftRows} \circ \text{SubBytes} \circ \theta_2 \circ \kappa(X)$, where $X$ is the round input state. In the last round, the $\pi$ operation is replaced by an additional AddRoundKey (round subkey $k_f$). We refer to [1] for more details of 3D structure. Because AddRoundKey and MixColumns operations are both linear, it is possible to replace them by each other. In such a case, we have an equivalent round subkey $k'' = \pi(k)$.

Notations. The specific bytes are indicated by brackets; for example bytes 2 and 8 of the round subkey $k_f$ are indicated by $k_{[2,8]}$. $x_i^\theta$, $x_i^\kappa$, $x_i^\pi$ denote the intermediate values after the application of SubBytes, ShiftRows, MixColumns and AddRoundKey operations of round $i$, respectively. Moreover, $x_i^\kappa$ is used to denote the AddRoundKey operation with the equivalent round subkey $k''$.

III. NEW 6-ROUND IMPOSSIBLE DIFFERENTIAL OF 3D

The impossible differential attack presented in this paper is based on a new 6-round impossible differential. As illustrated in Fig. 1, this distinguisher begins in the input of AddRoundKey operation of round 3 with a difference which is nonzero in any desired three bytes of the 16-th column and is zero in the other 61 bytes. So, there exist four different types of the input difference. Fig. 1 shows how one of these input differences leads to a difference in the output of round 5 which is zero in one slice and nonzero in the others. On the other hand, in the decryption direction, the distinguisher starts in the output of ShiftRows of round 8 with a difference which is nonzero in only one byte of the 16th column and zero in the other 63 bytes. Fig. 1 shows one of the four possible output differences leading to a difference which is nonzero in all 64 bytes in the output of round 5. This contradicts the output difference of the differential in the encryption direction.

IV. IMPOSSIBLE DIFFERENTIAL ATTACK ON 11 ROUNDS OF 3D

For mounting the impossible differential attack on 3D cipher, three rounds are added to the beginning of the 6-round distinguisher and two rounds to the end of it. Fig. 2 and Fig. 3 illustrate these added rounds, respectively. As it can be seen, 62 bytes of subkeys are involved in this attack and the ultimate goal is to recover the correct value of these subkeys. The attack scenario is composed of two phases. At the first stage some tables are pre-computed and then the online stage begins.

An issue, which must be considered in the online stage, is the amount of required proper plaintext/ciphertext pairs. Proper pairs are the plaintext/ciphertext pairs which satisfy the input difference $\Delta P$ and output difference $\Delta C$ as it is indicated in Fig. 2 and 3, respectively. Based on Fig. 2, the probability for a plaintext pair with the difference $\Delta P$ to meet the input difference of the distinguisher is about $2^{-192} \times 2^{-48} \times 4 \times 2^{-4} = \ldots$
2\(^{-246}\). For a ciphertext pair with the difference \(\Delta C\) the probability to meet the output difference of the distinguisher is also about \(2^{-96} \times 4 \times 2^{-24} = 2^{-118}\). So, for a proper plaintext/ciphertext pair, the probability to meet the impossible differential is about \(2^{-246} \times 2^{-118} = 2^{-364}\). For a specific value of the 62-byte target subkey, if a proper plaintext/ciphertext pair meets the impossible differential, then the value of subkey is wrong and must be eliminated from the key space. Therefore, using \(2^n\) proper pairs, the probability for a wrong key not to be eliminated is about \((1 - 2^{-364})^{2^n}\). So, using \(2^n\) proper pairs, about \(2^{46} \times (1 - 2^{-364})^{2^n}\) wrong 62-byte subkeys remain in the key space. For \(n = 372.43\), there will remain only about one wrong subkey (in addition to the correct subkey which is not eliminated). In the two upcoming subsections, at first, some required precomputations are described and then we will illustrate the online attack procedure.

A. Precomputations

In this section, we prepare three tables \(H_1, H_2\) and \(T\) to reduce the amount of partial encryption/decryptions in the online stage of the attack.

- \(H_1\): For all of the \(2^{6\times3} \times (2^8 \times (2^8 - 1))\) \(2^{40}\) possible pairs of \(\{x_0^\pi \in \mathbb{F}_{20}^{61,61,62,63}, x_1^\pi \in \mathbb{F}_{20}^{61,61,62,63}\}\) which have non-zero difference only in byte 60, compute the values of pairs \(\{x_0^\pi \in \mathbb{F}_{20}^{61,61,62,63}, x_1^\pi \in \mathbb{F}_{20}^{61,61,62,63}\}\). Store the obtained pairs in a hash table \(H_2\) indexed by their difference \(x_0^\pi \oplus x_1^\pi \in \mathbb{F}_{20}^{61,61,62,63}\). Such a table has \(2^{32}\) rows and on average \(2^{40}/2^{32} = 2^8\) pairs lie in each row. So, for an intermediate pair \(\{x_0^\pi \in \mathbb{F}_{20}^{61,61,62,63}, x_1^\pi \in \mathbb{F}_{20}^{61,61,62,63}\}\) it is sufficient to access the row indexed by \(x_0^\pi \oplus x_1^\pi \in \mathbb{F}_{20}^{61,61,62,63}\) in \(H_2\) to obtain on average \(2^8\) values for \(k_{1|\mathbb{F}_{20}^{61,61,62,63}}\). Note that we can also use table \(H_2\) to obtain on average \(2^8\) values of \(k_{1|60,49,54,59}\) for each plaintext pair of \(\{x_0^\pi \in \mathbb{F}_{20}^{61,61,62,63}, x_1^\pi \in \mathbb{F}_{20}^{61,61,62,63}\}\) which take this pair to a difference \(\Delta x_{1|\mathbb{F}_{20}^{61,61,62,63}}\) with only one non-zero byte in location 60.

- \(T\): For all of the \(2^{32}\) possible pairs of \(\{x_0^\pi \in \mathbb{F}_{20}^{61,61,62,63}, x_1^\pi \in \mathbb{F}_{20}^{61,61,62,63}\}\) with non-zero difference, perform a partial encryption through \(\pi \oplus \theta_1 \circ \gamma\) to compute the difference value \(\Delta x_{0|\mathbb{F}_{20}^{61,61,62,63}}\). Now, if this difference is non-zero exactly in three bytes, then store the pair in the table \(T\) indexed by \(x_0^\pi \oplus x_1^\pi \in \mathbb{F}_{20}^{61,61,62,63}\). The probability to meet this condition is about \(4 \times 2^{-8} = 2^{-3}\), so about \(2^{32} \times 2^{-3} = 2^{29}\) pairs lie in each of the \(2^{16}\) rows of table \(T\). Clearly, for an intermediate pair \(\{x_0^\pi \in \mathbb{F}_{20}^{61,61,62,63}, x_1^\pi \in \mathbb{F}_{20}^{61,61,62,63}\}\) it is sufficient to access the row of \(T\) with index \(x_0^\pi \oplus x_1^\pi \in \mathbb{F}_{20}^{61,61,62,63}\) to obtain on average \(2^{10}\) values for \(k_{1|\mathbb{F}_{20}^{61,61,62,63}}\).

The overall computations for preparing these tables are less than \(2^{41}\) partial encryptions. Further, the required memory for these tables is about \(2^{33}, 2^{43}\) and \(2^{28}\) bytes for the tables \(H_1, H_2\) and \(T\), respectively.

B. The online stage of the attack procedure

After preparing the hash tables, the attack is carried out by the following steps. In the first step of the attack the required proper plaintext/ciphertext pairs are prepared. Then, attack proceeds by removing wrong values of involved 62-byte subkeys from the key space until only the right value of the 62-byte subkey remains. For reducing the time complexity, we use the early aborting technique [16] as well as the precomputed tables \(H_1, H_2\) and \(T\). The overall required computations for each step (with respect to the 11-round 3D encryptions) are indicated in the end of that step. Also, in the following time complexities, the coefficient \(\alpha\) equals to \(2 \times (1/11) \times (1/16) \approx 2^{-4.6}\).

- Step 1. Take \(2^{373}\) structures of ciphertexts such that each structure contains about \(2^{128}\) ciphertexts that are fixed in the 48 bytes of \(\Delta C\) with zero difference indicated in Fig. 3 and take all the possible values in other 16 bytes. So, about \(2^{128} \times 2^{128}/2 = 2^{255}\) ciphertext pairs are obtained from each structure which their difference is coincident to the required \(\Delta C\). Obtain the corresponding plaintexts of each structure in a chosen ciphertext scenario. Since the probability of having a plaintext
pair with the difference $\Delta P$ in Fig. 2 is $2^{-256}$, then for each structure we can collect about $2^{255} \times 2^{-256} = 2^{-1}$ plaintext pairs with the difference $\Delta P$. Hence, after examining all of the $2^{373.43}$ structures, we can collect about $2^n = 2^{373.43} \times 2^{-1} = 2^{372.43}$ distinct ciphertext/plaintext pairs satisfying the desired $\Delta C$ and $\Delta P$, respectively. As it was discussed in the beginning of Section IV, this amount of data is sufficient to recover the correct value of 62-byte subkey. The time complexity of this step, which corresponds to the data complexity of the attack, is about $2^{128} \times 2^{373.43} = 2^{501.43}$ 11-Round 3D encryptions. We also need $4 \times 2^{372.43} \times 64 = 2^{380.43}$ bytes of memory to store the proper ciphertext/plaintext pairs.

- Steps (2, 3, 4, 5). For $i = 0, 1, 2$, do the following steps 2, 3, 4 and 5 sequentially:

Guess 32 bits of $k_{1[13,16], 6,16,9,16,12,16}$ and for all of the $2^{n-24}$ proper ciphertext pairs $(X^{eq}_{10,12,13,14,16,15,16}, X^{eq}_{10,12,13,16,14,16,15,16})$, perform a partial decryption to obtain the pairs $(X^{eq}_{10,15,30,45,60}, X^{eq}_{10,15,30,45,60})$. If for a proper pair, the difference of the obtained pairs is non-zero only in the byte $\Delta x^{eq}_{10,15,30,45,60}$, then keep this proper pair for the next step. The probability of this condition is about $2^{-24}$. So, about $2^{n-24-4(i+1)}$ proper pairs remain for the next step. The time complexity of this step is about $2^{-24}$, so there remain about $2^{n-24(i+1)}$ proper pairs for the next step. The time complexity of this step is about $2^{n-24-4(i+1)} = 2^{n-32+8i}$.

- Step 6. Now, we have the intermediate remaining pair values $(X^{eq}_{10,15,30,45,60}, X^{eq}_{10,15,30,45,60})$. Guess 32 bits of $k_{10,15,30,45,60}$ and for all the $2^{n-96}$ remaining pairs $(X^{eq}_{10,15,30,45,60}, X^{eq}_{10,15,30,45,60})$, perform a partial decryption to obtain the difference value $\Delta x^{eq}_{10,15,30,45,60}$. If for a pair, this difference is non-zero in only one byte, then we have met the desired difference in the output of the distinguisher in Fig. 1, so keep such a pair for the next step. The probability of this condition is about $4 \times 2^{-24}$, so it is expected to remain about $2^{n-118}$ proper ciphertext pairs which meet the output difference of the distinguisher. This step requires about $\alpha \times 2^{(n-96)-160} = \alpha \times 2^{n-56}$ correct encrypted pairs.

- Steps (7, 8, 9, 10). For all of the $2^{n-118}$ remaining ciphertext pairs take their corresponding plaintext pairs. Then for $i = 0, 1, 2$, do the following steps 7, 8, 9 and 10 sequentially:

Guess four bytes $k_{0,16], 3,16,10,16,15,16}$ and for all of the $2^{n-118-24}$ remaining proper plaintext pairs $(X_{0,16], 3,16,10,16,15,16}, X'_{0,16], 3,16,10,16,15,16})$ perform a partial encryption to obtain pairs $(X'_{16], 1,16,1,16,1,16,16,1,16,16,1,16,16})$. If for a pair, the difference value of $\Delta x^{eq}_{16], 1,16,1,16,1,16,1,16,1,16,1,16,1,16,1,16}$ is non-zero and the difference of the other three bytes of $(1 + 4i)$-th column of $\Delta x^{eq}_{16}$ are zero, then store this pair for the next step. The probability of this condition is about $2^{-24}$, so about $2^{n-118-24(i+1)}$ correct pairs remain for the next step. This step requires about $\alpha \times 2^{(n-118-24(i+1)+160)-128} = \alpha \times 2^{n-32+8i}$ correct encrypted pairs.

- Steps (11, 12, 13). So far, we have guessed 288 bits of subkeys and obtained about $2^{n-214}$ remaining pairs from previous steps. For $i = 0, 1, 2$, do the following steps 11, 12 and 13 sequentially:

Guess four bytes $k_{1[16,1,16,1,16,1,16,1,16,1,16,1,16,1,16,1,16]}$ and for all of the $2^{n-214-24i}$ remaining plaintext pairs $(X_{0,16], 1,16,1,16,1,16,1,16,1,16,1,16,1,16,1,16}, X^{eq}_{12,16,1,16,1,16,1,16,1,16,1,16,1,16,1,16})$. If for a pair, the difference value of $\Delta x^{eq}_{12,16,1,16,1,16,1,16,1,16,1,16,1,16,1,16}$ is non-zero and the difference of the other three bytes of 4$(i + 1)$-th column of $\Delta x^{eq}_{12}$ are zero, then store this pair for the next step. The probability of this condition is about $2^{-24}$. So, about $2^{n-214-24} = 2^{n-24}$. Proper pairs remain for the next step. About $\alpha \times 2^{n-214-24} = 2^{n-24}$ correct encrypted pairs are performed in this step.

- Step 14. So far, we have guessed 384 bits of subkeys and obtained about $2^{n-286}$ remaining pairs from previous steps. Prepare a vector $U$ of $2^{117}$ bits, each corresponds to a possible value of 112 bits $k_{0,16,9,16,10,16,15,16} \{k_{1,48,1,18,35}, k_{0,60,13,30,47}, k_{2,60,49}\}$. Now, for each of the $2^{n-286}$ remaining pairs do the following steps:

- Step 14.1. In this step, we have the intermediate pair values $(x^{eq}_{14,18,18,35}, x^{eq}_{14,18,18,35})$. So, by reference to the row indexed by $x^{eq}_{14,18,18,35}$ in table $H_1$, obtain 28 values for $k_{1,48,18,35}$. Then, for these key values make a partial encryption to obtain corresponding 28 pairs values $(x^{eq}_{2,49}, x^{eq}_{2,49})$. The time complexity of this step is $2^{384+(n-286)-8} = 2^{n+106}$ correct encrypted pairs.
step requires $2^{384+(n-286)+8+8} = 2^{n+114}$ MA and $\alpha \times 2^{n+114}$ encryptions.

- **Step 14.4.** For each of the $(2^6 \times 2^8) \times 2^8$ obtained pair values $(x^y_{j,1(60,49)} \times x^y_{j,2(60,49)})$, access to the row indexed by $x^y_{j,2(60,49)} \oplus x^y_{j,2(60,49)}$ in table T to obtain $2^{10}$ values for $k_{j,1(60,49)}$. Then, for each of the $2^8 \times 2^8 \times 2^8 \times 2^{40} = 2^{34}$ obtained subkey values $k_{j,1(60,49),549} \cdot k_{j,1(60,33,30,4)} \cdot k_{j,2(60,49)}$ mark the corresponding bits in the vector U to indicate them as wrong keys. This step requires $2^{384+(n-286)+34} = 2^{n+112}$ MA.

- **Step 15.** Check all of the bits of the vector U and if there is a bit that is not marked, you have found a candidate for the correct 496-bit subkey which consists of the corresponding 112-bit value of this unmarked bit along with the current 384-bit guessed subkey. So, store this candidate and continue the procedure. This step requires $2^{84+112} = 2^{496}$ MA.

As it is expected, the above procedure proceeds until all of the $2^{384}$ possible values of 384-bit subkeys are guessed in order. It is expected that eventually, there will remain about 2 candidates for the correct 496-bit target subkey. For each candidate, 256 bits of these 496 bits are the bits of $k_0$. Finally, for each candidate we perform an exhaustive search for the other 256 bits of $k_0$ with $2 \times 2^{256}$ 11-round encryptions.

### C. Complexity of the attack

As mentioned in Step 1 of the online stage of the attack, the required data to mount the attack contains approximately $2^{328} \times 2^{373,43} = 2^{501,43}$ chosen plaintexts. The memory complexity consists of $4 \times 2^{372,43} \times 64 = 2^{380,43}$ bytes of memory to store the proper ciphertext/plaintext pairs, $2^{112}$ bits to store the U vector in step 14, and about $2^{44}$ bytes for the precomputed tables. Also, note that the required memory for storing the intermediate pairs is far less than $2^{380,43}$ bytes of memory, hence the total memory complexity is about $2^{381}$ bytes of memory.

As mentioned in the online stage of the attack, for $n = 372,43$, the dominant parts of the time complexity include $2^{384,43}$ MA in Step 14-4, $2^{496}$ MA in Step 15, and $2^{487,97}$ 11-round 3D encryptions in step 13. On the other hand, for each round of 3D, transformations $\gamma$ and $\pi$ can be evaluated by 64 and 16 memory accesses, respectively. In a same way, according to the key schedule of 3D, described in [1], each round key $k_j$ to $k_l$ is obtained with $16 + 16 = 32$ memory accesses. Thus, the application of 11-round encryptions requires about $(11 \times 64 + 10 \times 16) + 11 \times 32 = 1216 \approx 2^{10.25}$ memory accesses (The complexity of key additions and byte permutations are negligible).

Hence, the total time complexity is equivalent to about $2^{505-10.25} + 2^{488} \approx 2^{495}$ 11-round encryptions. However, if we increase the number of remaining candidates from one candidate to about $2^{330}$ candidates, then according to the corresponding equality $2^{106} \times (1-2^{-364})^2 = 2^{230}$, the data complexity decreases to about $2^{500,43}$ chosen plaintexts. Due to this change, the only affected part of time complexity is the complexity of the exhaustive search (after the last step) with $2^{320} \times 2^{256} = 2^{486}$ 11-round encryptions, which does not change the overall time complexity of the attack.

### V. Conclusion

Security of 3D block cipher has been considered through several cryptanalysis methods. The best known single-key attack on 3D is a truncated differential attack on 13 rounds of this cipher which has been proposed by Takuma et al. [5], with the time complexity of $2^{308}$ encryption and data complexity of $2^{470}$ chosen plaintexts. In this paper, we focused on advancing the impossible differential cryptanalysis of 3D block cipher. While the previous impossible differential attacks on this cipher can analyze up to 10 rounds of the cipher, this paper, using a new 6-round impossible differential, presents an impossible differential attack on 11-round variant of 3D. The proposed attack requires about $2^{301}$ chosen plaintexts and about $2^{381}$ bytes of memory. Also, the overall time complexity of the attack is equivalent to about $2^{495}$ 11-round encryptions of 3D.
